ABSTRACT

Energy dissipation rates during ocean wave breaking are estimated from high-resolution profiles of turbulent velocities collected within 1 m of the surface. The velocity profiles are obtained from a pulse-coherent acoustic Doppler sonar on a wave-following platform, termed a Surface Wave Instrument Float with Tracking, or ‘SWIFT’, and the dissipation rates are estimated from the structure function of the velocity profiles. The purpose of the SWIFT is to maintain a constant range to the time-varying surface and thereby observe the turbulence in breaking crests (i.e., above the mean still water level). The Lagrangian quality is also useful to pre-filter wave orbital motions and mean currents from the velocity measurements, which are limited in magnitude by phase-wrapping in the coherent Doppler processing. Field testing and examples from both offshore whitecaps and nearshore surf breaking are presented. Dissipation is elevated (up to $10^0 \text{ W/m}^3 [= 10^{-3} \text{ W/kg}]$) during strong breaking conditions, which are confirmed using surface videos recorded onboard the SWIFT. Although some velocity contamination is present from platform tilting and heaving, the structure of the velocity profiles is dominated by a turbulent cascade of eddies (i.e., the inertial sub-range). The noise, or uncertainty, in the dissipation estimates is shown to be normally distributed and uncorrelated with platform motion. Aggregated SWIFT measurements are shown to be useful in mapping wave breaking dissipation in space and time.

1. Introduction

The breaking of ocean surface waves generates strong turbulence and energy dissipation. In deep water, breaking participates in air-sea exchange and limits wave growth (Banner and Peregrine 1993; Melville 1996). In shallow water, breaking suspends sediment, forces currents, and drives coastal morphology (Battjes 1988). Although the mechanisms differ, both types of breaking are effective at dissipating wave energy in the form of turbulent kinetic energy (Herbers et al. 2000).

Field observations of deep water breaking (i.e., whitecaps) have shown that turbulent dissipation is a function of wave steepness and is correlated with wind stress (Terray et al. 1996; Gemmrich and Farmer 1999, 2004; Gerbi et al. 2009; Thomson et al. 2009; Gemmrich 2010). Field observations of shallow water breaking (i.e., surf) have shown that turbulent dissipation is a function of water-depth and is correlated with the energy flux gradient of shoreward swell (Trowbridge and Elgar 2001; Bryan et al. 2003; Feddersen 2011). These observations typically are made using fixed instruments mounted bellow the mean (still) water level. Thus, it has been difficult to estimate turbulent dissipation near the time-varying wave surface. Recently, Gemmrich (2010) used up-looking Doppler sonars to estimate dissipation within breaking wave crests and found dissipation rates ten times higher than those measured below the mean water level.

Here, the method of Gemmrich (2010) is adapted to wave-following reference frame using a new Lagrangian drifter. The drifter, which is termed a Surface Wave Instrument Float with Tracking (SWIFT), is designed to follow the time-varying free-surface while collecting high-resolution profiles of turbulent velocity fluctuations. The velocity fluctuations are used to estimate the turbulence dissipation rate following Wiles et al. (2006). Thus, the SWIFT measurements can be used to estimate both wave spectra (from the drifter motions) and wave breaking dissipation (from the Doppler velocity profiles). Previously, drifters have been used in the nearshore to observe currents (Schmidt et al. 2003; MacMahan et al. 2009), as well as particle dispersion (Spydell et al. 2007). Drifters also have been used in the open

28 ocean to observe wave breaking and air-sea exchange (Graber et al. 2000; Pascal et al. 2011).
29 In addition to a Lagrangian reference frame, drifters have the advantage of measurement in
30 the absence of ship interference (e.g., wave reflections from the hull).

31 The SWIFT platform and raw data collection are presented in §2. Then, processing
32 methods for wave spectra and turbulent dissipation rates are described in §3, with an em-
33 phasis on separating platform motion from turbulence. These methods are demonstrated
34 in §4 with data from two field tests: (a) shallow water surf at the Field Research Facility
35 in Duck NC, and (b) deep water whitecaps on Lake Washington in Seattle WA. Examples
36 from individual ‘bursts’ with strong and weak breaking are compared for each test, and
37 results from all ‘bursts’ are aggregated to examine patterns in wave breaking dissipation.
38 For the Lake Washington tests, an independent measurement of the wave-breaking turbulent
39 dissipation rate at one point in the vertical profile is obtained using an acoustic Doppler ve-
40 locimeter (ADV) onboard the SWIFT. Discussion of the test results and data quality follow
41 in §5 and conclusions are given in §6.

42 **2. Data collection**

43 The Surface Wave Instrument Float with Tracking (SWIFT) is shown in Figure 1. The
44 purpose of the SWIFT is to make measurements in a wave-following reference frame. The
45 primary dimensions are: 2.15 m length overall (1.25 m draft + 0.9 m mast) and 0.3 m
46 diameter hull. Onboard instruments include: a GPS logger (QStarz BT-Q1000eX), a pulse-
47 coherent Doppler velocity profiler (Nortek Aquadopp HR), an autonomous meteorological
48 station (Kestrel 4500), and a digital video recorder (GoPro Hero). The SWIFT location is
49 tracked in realtime with a radio frequency transmitter (Garmin Astro). SWIFT missions
50 typically last several hours, up to a full day, and data are collected in five-minute bursts.

51 *a. Platform motion*

52 The SWIFT wave-following motion is measured via GPS logger (QStarz BT-Q1000eX)
53 at 5 Hz. Although the absolute horizontal accuracy of the DGPS positions is only 10 m,
54 the relative horizontal velocity resolution is much higher (0.01 m/s) and suitable for the
55 orbital motions of most ocean waves. The GPS vertical elevation accuracy is not sufficient
56 to track wave-following motion, however relative (i.e., in the wave reference frame) vertical
57 information is available from the pressure and orientation sensors in the Nortek Aquadopp
58 HR. The Aquadopp pressure is equivalent to the SWIFT surface tracking, and pitch and
59 roll are equivalent to the components of the SWIFT vertical tilting. (Constant values from
60 these sensors indicate good wave-following behavior.) The GPS and Aquadopp orientation
61 data are processed to determine the wave-height spectra and the quality of wave-following
62 (see §3a).

63 In addition to wave-following motions, the SWIFT oscillates, or ‘bobs’, at a natural
64 frequency. The SWIFT has 12.7 Kg buoyancy in the main hull (0.3 m diameter, see Figure
65 1) and 2.6 Kg of lead ballast at the bottom of the lower hull (i.e., 1.25 m below the surface).
66 Following Middleton et al. (1976), the corresponding theoretical natural period is $T_n \approx 1.3$
67 s, which intentionally is shorter than most ocean waves. This natural oscillation is damped
68 by a heave plate at the bottom of the lower hull (see Figure 1).

69 While wave-following, the SWIFT also drifts with mean currents and wind. Tests in
70 Puget Sound, WA, under a range of tidal currents from 0.4 to 2.2 m/s, indicate drift velocities
71 are consistent with fixed ADCP observations (not shown). Wind drag causes the SWIFTs
72 to drift with the wind, which is measured onboard the SWIFT at 0.9 m above the surface,
73 at about 5% of the wind speed (as empirically determined from tests in 0 to 14 m/s winds).
74 While drifting, a sub-surface vane on the lower hull (see Figure 1) provides additional drag to
75 maintain an orientation such that the video and Aquadopp beam 1 look upwind (or upwave,
76 for locally generated wind-waves). Under strong winds, the drag of the 0.9 m mast causes a
77 steady tilt of the SWIFT relative to the vertical (see picture in Figure 1). This tilt changes

78 slightly the vertical projection of sub-surface velocity profiles (next section), but otherwise
79 has negligible effects.

80 *b. Turbulence profiles, $u'(z)$*

81 Turbulent velocity profiles $u'(z)$ are obtained with a 2 MHz Nortek Aquadopp HR (pulse-
82 coherent) Doppler profiler. The Lagrangian quality of the drifter is motivated, in part, by
83 range and magnitude limitations in the Doppler measurements of $u'(z)$. The Aquadopp
84 is mounted in the lower hull and collects along-beam velocity profiles at 4 Hz with 0.04 m
85 vertical resolution along a 0.8 m beam. Bursts of 1024 profiles (=256 s) are collected at 300 s
86 intervals. The beam is orientated up and outward, at an angle of 25° relative to vertical (see
87 Figure 1), and the SWIFT is vaned to keep this beam looking up-wave (to avoid measuring
88 the drift wake of the SWIFT). In field testing, wave reflections from the main hull of SWIFT
89 are not observed, presumably because the SWIFT is moving with the free surface. The
90 blanking distance next to the transducer is 0.1 m, and thus the actual beam profile is 0.7 m
91 long.

92 A major concern with up looking Doppler measurements is interference from surface re-
93 flections. This is especially significant for coherent systems. Profiles of alongbeam backscat-
94 ter amplitude and coherence are used to look for interference, which would appear as a peak
95 in amplitude and reduction in coherence at specific location in the profile (corresponding to
96 a returning pulse interfering with an outgoing pulse). Using a pulse distance of 0.8 m, which
97 is similar to actual distance to the surface, is the minimum value that can be used. Field
98 testing (§4) does not indicate any interference for surface reflections.

99 The velocity data are quality-controlled using a minimum pulse correlation value of $c > 50$
100 (out of 100) and a minimum backscatter amplitude $a > 30$ counts, which were empirically
101 determined to be the maximum values associated with spurious points and with bins out
102 of the water. Nortek notes that a canonical value of $c > 70$ is often overly restrictive, and
103 recommends $c > 50$ as a more useful cutoff (Rusello 2009). For Acoustic Doppler Velocimeter

104 (ADV) measurements, an accepted threshold is $c > 30 + 40\sqrt{f_s/f_{max}}$, where f_s and f_{max}
 105 are the actual and maximum possible sampling frequencies, respectively (Elgar et al. 2001;
 106 Feddersen 2010). Although ADVs are point measurements, instead of profile measurements,
 107 ADVs operate on the same coherent processing between pulse pairs to determine the Doppler
 108 shift and thus velocity. Applying the threshold here, using $f_s = 4$ Hz and $f_{max} = 8$ Hz, gives
 109 threshold of $c > 58$, similar to the ad hoc choice of $c > 50$. This choice of correlation cutoff
 110 is evaluated in §5 by comparing the sensitivity of results obtained in post-processing with
 111 cutoff values of $c > 0, 25, 50,$ and 75 .

112 Observations with $c < 50$ or $a < 30$ are assigned NaN velocity values and ignored during
 113 subsequent analysis (i.e., no interpolation). At worst, the quality control ratio of points
 114 removed to total points is 1:2, or half of the data in a given burst. Even in these cases with
 115 significant data removal, there are at least 512 profiles remaining with which to determine
 116 the average structure of the turbulence. More often, the quality control ratio is less than
 117 1:10.

118 The velocity data also are quality-controlled by examining the Extended Velocity Range
 119 (EVR) data in the HR mode, which uses a second, shorter pulse lag to obtain a wider velocity
 120 range at point in the middle of the profile. Here, the pulse distances are 0.8 and 0.26 m, and
 121 the along-beam velocity range is 0.5 m/s. Comparing the profile and EVR data is essential
 122 to confirm that phase wrapping has not occurred. Comparing the profile and EVR data also
 123 is useful to evaluate quality-control via coherence and amplitude thresholds (i.e., for data
 124 within the velocity range, points with low correlations c or amplitudes a should be the only
 125 points that do not compare well).

126 The pulse-coherent measurements from the Aquadopp HR do not have a nominal Doppler
 127 uncertainty, or ‘noise’, value. Zedel et al. (1996) show that noise is a function of the coherence
 128 of each pulse pair, as well as sampling parameters (i.e., rate, number of bins) that control
 129 phase resolution. Still, a nominal value is useful when interpreting results. Here, a nominal
 130 velocity uncertainty (standard error) of $\sigma_{u'} = 0.025$ m/s is used, which is 5% of the along-

131 beam velocity range and similar to the $\sigma_{u'} = 0.02$ m/s reported by Zedel et al. (1996) for
 132 a correlation $c = 50$. In practice, the noise is not prescribed, but rather is retained as a
 133 free parameter in the solution for the dissipation rate (§3c). The empirical noise is later
 134 compared with the nominal variance of $\sigma_{u'}^2$ to evaluate results (§5).

135 The along-beam velocities are mapped, but not projected, to a vertical coordinate z for
 136 subsequent processing and plotting (i.e., each value of u' is unchanged, but is assigned a z
 137 location). The z location is defined as the distance beneath the instantaneous free surface
 138 ($z = 0$) and the Aquadopp pressure gage (also sampled a 4 Hz) is used to correct for any
 139 changes in the waterline level at the SWIFT. This correction is small (a result of the wave
 140 following nature of the platform), and never shifts the observed profile up or down more
 141 than one profile bin (i.e., ± 0.04 m).

142 3. Methods

143 The SWIFT drifters are designed to make in situ observations of velocity u that can be
 144 decomposed as

$$u = \bar{u} + \tilde{u} + u', \quad (1)$$

145 where \bar{u} is the time mean velocity, \tilde{u} are the wave orbital velocities, and u' are the turbulent
 146 fluctuations of velocity that are processed to estimate dissipation rates. In practice, the
 147 mean and wave orbital velocities are horizontal vectors in the earth reference frame, and the
 148 turbulence measurements are scalar along-beam components in the wave-following reference
 149 frame (see Figure 1). SWIFT data are parsed into five-minute bursts for processing, and $\langle \rangle$
 150 notation will be used to denote burst ensembles. Overbars will be used for burst-averaged
 151 quantities. For example, the SWIFT GPS velocities are averaged to determine the mean
 152 drift velocity $\bar{u} = \langle u \rangle$. These bursts are sufficiently short to have quasi-stationary statistics
 153 (i.e., steady mean and variance), but long enough to have meaningful confidence intervals
 154 on calculated quantities. Given a typically drift speed of $\bar{u} \sim 0.2$ m/s, a SWIFT drifts

155 approximately 60 m during a burst. The burst-averaged quantities must assume homogeneity
 156 over this scale, which may be a poor assumption in a region of rapidly evolving waves (e.g.,
 157 the surfzone).

158 The wave-following behavior of the SWIFTs, which separates wave orbital velocities \tilde{u}
 159 from turbulent fluctuations u' , is essential to the estimates of wave spectra and turbulent
 160 dissipation rates, respectively. These quantities, and the quality of wave-following, are de-
 161 scribed in the next two sections.

162 *a. Frequency spectra, $S(f)$*

163 Frequency spectra $S(f)$ are used to evaluate the motion of the SWIFT and to quantify
 164 the wave conditions. Spectra for each five-minute bursts are calculated as the ensemble
 165 average of the Fast Fourier Transform (FFT) of 16 sub-windows with 50% overlap, which
 166 resulting in 32 degrees of freedom and a frequency bandwidth $df = 0.0625$ Hz.

167 Spectra from Aquadopp orientation data (i.e., pitch, roll, and heading), $S_{\theta\theta}(f)$, are used
 168 to assess the tilting and turning of the SWIFT during wave-following. In field testing (§4),
 169 the orientation spectra $S_{\theta\theta}(f)$ does show broad peaks at the natural period of the platform
 170 and at the period of the waves. However, the more prominent signals are the trends caused
 171 by shifting winds and surface currents (i.e., low frequencies). These platform motions shift
 172 the entire Aquadopp profile $u'(z)$ with an offset Δu_θ , which has a negligible affect of the
 173 structure of $u'(z) - u'(z + r)$ (see next section).

174 Spectra from the Aquadopp pressure data (i.e., relative distance below the surface),
 175 $S_{pp}(f)$ are used to assess the surface tracking of the SWIFT during wave-following. In field
 176 testing (§4), the natural frequency (~ 0.7 Hz) is the dominant peak in the pressure spectra
 177 $S_{pp}(f)$, and wave peaks are negligible (i.e., pressure fluctuations from waves are absent in the
 178 wave-following reference frame). Integrating $S_{pp}(f)$ around the natural frequency estimates
 179 the variance in the surface tracking owing to ‘bobbing’ of the platform. In field testing, this
 180 variance is typically $O(10^{-4} \text{ m}^2)$, or a vertical standard deviation of 0.01 m.

181 In contrast, the SWIFT GPS horizontal velocity data contain the wave orbital motions
 182 relative to the earth reference frame. Thus, the wave orbital velocity spectra $\int S_{\bar{u}\bar{u}}(f)df =$
 183 $\langle(u - \bar{u})^2\rangle$ is used to estimate the underlying wave conditions. The scalar wave height spectra
 184 $S_{\eta\eta}(f)$ can be calculated from $S_{\bar{u}\bar{u}}$ using linear finite-depth theory (Mei 1989), if the water
 185 depth is known from another source. In deep water, the conversion is simply $S_{\eta\eta}(f) =$
 186 $S_{\bar{u}\bar{u}}(f)(2\pi f)^{-2}$. In practice, this is done component-wise, with the total scalar spectrum
 187 equal to the sum of the converted spectrum of the two orthogonal velocity components.

188 Finally, spectra of the Doppler turbulent velocity profiles $S_{u'u'}(f)$ are used to look for
 189 contamination from SWIFT motion. Even for perfect wave-following, the $S_{u'u'}(f)$ spectra
 190 will have a peak at the natural frequency of the SWIFT, similar to the pressure spectra.
 191 For cases with significant tilt and rotation contamination, the $S_{u'u'}(f)$ spectra may have
 192 a peak at wave orbital frequencies as well. The relevant quantity for estimating turbulent
 193 dissipation, however, is the difference between points in the velocity profile $u'(z) - u'(z + r)$
 194 (see next section). The velocity differences (i.e., the turbulence) along a profile are much
 195 less susceptible to motion contamination, because platform motion contaminates the entire
 196 profile (i.e., an offset). Thus, spectra of velocity differences at selected points along the profile
 197 are used to evaluate the motion contamination of the turbulence observations. In field testing
 198 (§4), velocity spectra show expected peaks, however velocity difference spectra lack wave or
 199 natural frequency peaks. The velocity difference spectra depend on the separation distance
 200 between velocity bins, and an increase in spectral energy density with increasing separation
 201 is consistent with the structure of a turbulent cascade.

202 *b. Turbulence structure function, $D(z, r)$*

203 The along-beam Doppler velocity profiles $u'(z)$ are processed to estimate the turbulent
 204 dissipation rate following the method of Wiles et al. (2006), in which the vertical second-order

205 structure function $D(z, r)$ of velocity fluctuations $u'(z)$ is defined as

$$D(z, r) = \langle (u'(z) - u'(z + r))^2 \rangle, \quad (2)$$

206 where z is the vertical location beneath the free surface, r is the along-beam distance between
 207 velocity fluctuations, and the bracket denotes the burst time-average (five minutes). This
 208 choice of time-scale obscures the details of a individual breaking events in favor of robust
 209 statistics on the overall effect of breaking (enhanced turbulent dissipation near the free
 210 surface). Note that variance in time is not significant to the structure function, other than
 211 as contamination by non-stationarity, because it is the difference of $u'(z)$ over spatial scales
 212 r that controls $D(z, r)$.

213 $D(z, r)$ is one-sided, such that differences are taken from the top of the profile downwards,
 214 and at least three valid velocity bins (i.e., three $z + r$ combinations) are required to obtain
 215 each $D(z, r)$ value. The range r is limited to half of the profile length or the distance
 216 to the boundary, whichever is smaller. As shown by Gemmrich (2010), estimation of the
 217 structure function beneath breaking waves is sensitive to the maximum separation scale $|r|$
 218 used, because turbulence may decay rapidly beneath the wave crests (i.e., heterogeneity).

219 *c. Dissipation rate profiles, $\bar{\epsilon}(z)$*

220 Assuming homogenous turbulence and a cascade of isotropic eddies in the inertial sub-
 221 range (Kolmogorov 1941), the dissipation rate of turbulent kinetic energy scales as $\epsilon \sim$
 222 $u'^2/T \sim u'^3/r$, where T is a time scale given by r/u' . Thus, the structure of the turbulence
 223 $D(z, r)$ should follow a power law $r^{2/3}$. Here, the burst estimates of $D(z, r)$ are fit to a linear
 224 model

$$D(z, r) = A(z)r^{2/3} + N, \quad (3)$$

225 where an A is determined for each z using MATLAB's robust fit algorithm and N is an
 226 offset due to measurement noise. The burst-averaged dissipation rate is then

$$\bar{\epsilon}(z) = \rho_w \mathcal{C}_v^{-3} A(z)^{3/2}, \quad (4)$$

227 where \mathcal{C}_v is a constant equal to 1.45. The offset N is expected to be $2\sigma_{u'}^2$, in which $\sigma_{u'}$ is
 228 the Doppler noise of the velocity measurement (Wiles et al. 2006; Rusello and Cowen 2011).
 229 Here, N values are obtained from robust linear fit (rather than prescribed) and are used to
 230 evaluate errors in the methods or violations in the assumptions (see §5). The N values are
 231 also used for quality control, by accepting only $N \ll Ar^{2/3}$.

232 The room-mean square error (RMSE) between the fitted $A(z)r^{2/3}$ and the actual structure
 233 $D(z, r)$ is propagated through Eq. 4 and used as the uncertainty in dissipation σ_ϵ . This
 234 uncertainty is asymmetric, because of the exponent in Eq. 4, and both upper and lower
 235 bounds are propagated as $\sigma_{\epsilon\pm}$. This uncertainty is used for another layer of quality control,
 236 by requiring that $|\sigma_{\epsilon\pm}| \ll \epsilon$.

237 The dissipation rate profile $\bar{\epsilon}(z)$ can be integrated to obtain the total dissipation rate per
 238 unit surface area,

$$\bar{E} = \int \bar{\epsilon}(z) dz. \quad (5)$$

239 This integral is limited by the lowest depth ($z \approx 0.5$ m) below the wave-following surface
 240 ($z = 0$ m). For some wave conditions, this limitation will be severe given the expectation
 241 that the depth breaking turbulence scales with wave height (Babanin 2011). However, in
 242 field testing (next section), dissipation rates are observed to decrease sharply beneath the
 243 wave following surface and linear extrapolation below $z = 0.5$ would rarely increase \bar{E} more
 244 than 10%. This is consistent with Gemmrich (2010), in which near-surface profiles of wave-
 245 resolved dissipation rates captured the full evolution of breaking turbulence within $z < 0.6$
 246 m. The uncertainties $\sigma_{\epsilon\pm}$ are summed in Eq. 5 to obtain asymmetric uncertainties in the
 247 ‘total’ dissipation, $\sigma_{E\pm}$.

248 Finally, in some of the field testing, another method to estimate the dissipation rate
 249 is incorporated to provide an independent comparison with the structure function method.
 250 The second method uses the common approach of rapidly sampled (32 Hz) acoustic Doppler
 251 velocimeter (ADV) data to calculate frequency spectra of turbulent kinetic energy (Lumley
 252 and Terray 1983; Trowbridge and Elgar 2001; Feddersen 2010). The frequency spectra are

253 converted to wavenumber spectra by assuming the advection of a frozen field (i.e., Taylor’s
 254 hypothesis), and the dissipation rate is obtained by fitting an amplitude B to the inertial
 255 sub-range of the spectra, $S_{ADV}(f) = Bf^{-5/3}$, and taking $\bar{\epsilon}_{ADV} = \rho_w \left(\frac{B}{(\bar{u}/2\pi)^{2/3\kappa}} \right)^{3/2}$. For
 256 implementation on the SWIFT, a Nortek Vector ADV was mounted at $z = 0.25$ m below the
 257 surface (see Figure 1), and the GPS-based drift velocity was used for the advection velocity
 258 \bar{u} . The Kolmogorov constant is $\kappa = 0.55$, and the RMSE in the fit is propagated to obtain
 259 asymmetric uncertainties on the $\bar{\epsilon}_{ADV}$ values (similar to the approach for uncertainties in $\bar{\epsilon}$
 260 from the structure function). The ADV method only estimates dissipation a single depth
 261 beneath the surface ($z = 0.25$ m), and thus is insufficient to evaluate the total dissipation
 262 (Eq. 5).

263 4. Field testing and examples

264 A series of field tests have been conducted to refine the SWIFT design and data processing
 265 algorithms. To date, six SWIFTs have been fabricated and approximately 400 hours of
 266 SWIFT data have been collected in testing. Select data and results from tests are presented
 267 in the following sections. First, shallow-water testing at the Duck Field Research Facility
 268 (FRF) is described. Second, deep-water testing on Lake Washington is described, which
 269 includes the ADV spectral dissipation estimates (for comparison with the Aquadopp HR
 270 estimates via the structure function). For each field test, individual burst data and processing
 271 are compared between weak and strong breaking conditions (as determined from the onboard
 272 video recordings), and then patterns from aggregate results using all bursts are examined.

273 a. *Shallow-water breaking (surf) at Duck FRF*

274 Field data were collected over four hours on 15 September 2010 at the US Army Corps
 275 of Engineers (US-ACE) Field Research Facility (FRF) in Duck, NC (USA). Conditions, as
 276 measured by FRF instruments were: onshore 2-5 m/s winds, 10 s period swell with 0.6 m

277 significant wave height. The FRF uses a local coordinate system, in which x is increasing
278 offshore and y is increasing alongshore. For these mild conditions and neap tides, the surfzone
279 was contained with $100 < x < 150$ m. SWIFTs were released from a small boat outside of
280 the surf zone (cross-shore distance $x \sim 250$ m, water depth $h \sim 4$ m) and allowed to drift
281 into the surf zone. SWIFTs eventually grounded on the beach and were recovered there. An
282 early version of the SWIFT was used, which differed slightly from the version in Figure 1.
283 The earlier version used a 90° transducer head on the Aquadopp HR, which was mounted
284 across the lower hull to achieve approximately the same beam geometry as the version in
285 Figure 1. All other sampling parameters were as described in previous sections.

286 Figure 2 show examples of the raw burst data (4 Hz for 5 minutes) from outside and
287 inside of the surf zone (left versus right panels). The surface elevation ($z = 0$) appears
288 constant in the lower panels because the SWIFT is following the free-surface. There is
289 a notable decrease in scatter for velocity measurements above the chosen correlation cutoff
290 $c > 50$ (upper panels of Figure 2). There also is improved agreement between the profile data
291 and the extended velocity range (EVR) data for velocity measurements above the chosen
292 correlation cutoff $c > 50$ (middle panels of Figure 2). The depth profiles do not show
293 any strong trends (lower panels of Figure 2). In particular, the profiles of amplitude and
294 correlation did not show any sharp features that would indicate interference from surface
295 reflections. The backscatter amplitude is uniformly increased in the surf zone example
296 ($a \sim 200$ counts) compared with the offshore example ($a \sim 150$ counts), consistent with the
297 presence of bubbles in the surf zone. The burst data outside of the surf zone include a brief
298 period (~ 20 s) with the instrument out of the water for repositioning, and this results in a
299 much higher quality control ratio (i.e., more points are removed from the velocity data prior
300 to processing).

301 Figure 3 shows examples of the spectra estimated from outside and inside of the surf
302 zone (left versus right panels). For this test, SWIFT GPS data were not sufficient quality to
303 estimate wave spectra, and wave spectra from a nearby FRF array instrument (an Aquadopp

304 at $x = 232$ m) are used. The SWIFT orientation spectra show a trend of more variance at
 305 lower frequencies, with no distinct peaks (upper panels of Figure 3). The SWIFT pressure
 306 spectra show an expected peak at a natural frequency of $f_n \approx 0.7$ Hz and no peak at
 307 wave frequencies, consistent with surface following motion (middle panels of Figure 3). The
 308 turbulent velocity spectra of a selected depth $z = 0.16$ m below the surface do show a peak
 309 at the natural frequency of the SWIFT, indicating the potential for motion contamination.
 310 However, the two selected velocity differences (between depths $[z, z + 0.04\text{m}]$ and $[z, z +$
 311 $0.16\text{m}]$) do not show contamination peaks (lower panels of Figure 3). Moreover, the velocity
 312 difference spectra show an expected increase in energy density between smaller ($z, z + 0.04\text{m}$)
 313 and larger ($z, z + 0.16\text{m}$) lag distances. It is these velocity differences that determine the
 314 structure function $D(z, r)$ and associated dissipation rates (Eqs. 2-4).

315 Figure 4 shows examples of the processing of turbulent velocity profiles outside and inside
 316 of the surf zone (left versus right panels). The structure function $D(z, r)$ is fit to $Ar^{2/3}$ at
 317 different depths z , and the slope A increases inside the surf zone (left versus right middle
 318 panels of Figure 4). The noise intercept N is small for all fits, and the RMSE error between
 319 the fits and the structure function is small. The resulting dissipation rate profiles $\bar{\epsilon}(z)$ are
 320 well-resolved and decrease away from the surface (lower panels of Figure 4). The depth-
 321 integrated dissipation rate \bar{E} in the surfzone is approximately 2.5 times larger than outside
 322 of the surfzone.

323 Figure 5 shows cross-shore bathymetry and the aggregated results of all SWIFT bursts
 324 on 15 September 2011, plotted as a function of cross-shore distance in the local FRF coor-
 325 dination system. With small incident waves and a weak (neap) low tide, the surfzone is at
 326 approximately $100 < x < 150$ m. (With larger waves and lower tides, the surfzone typically
 327 is farther offshore.) The vertically integrated dissipation rate estimates \bar{E} peak within the
 328 surfzone (middle panel of Figure 5). These ‘total’ dissipation rates likely neglect important
 329 significant dissipation occurring near the seabed (Feddersen 2011), which is discussed fur-
 330 ther in §5. In contrast, the noise in the structure function fits does not increase in the surf

331 zone (lower panel of Figure 5), suggesting that noise is not correlated with the dissipation
332 estimates, nor the SWIFT motions (both of which increase in the surf zone).

333 *b. Deep-water breaking (whitecaps) on Lake Washington*

334 Field data were collected over six hours on 12 November 2011 on Lake Washington in
335 Seattle, WA (USA). Conditions, as measured by nearby meteorological station (King County
336 bouy) and Waverider instruments were: southerly 8-10 m/s winds, 3 s period fetch-limited
337 waves with 0-1 m significant wave height. SWIFTs were released from a small boat just north
338 of the I-90 floating bridge in the middle of the lake and allowed to drift north along a fetch
339 distance x , where $x = 0$ is the location of the floating bridge. SWIFTs were in deep water
340 ($h > 30$) m at all times, as confirmed via post-processing of GPS positions with bathymetry
341 in Google Earth. As shown in Figure 1, this version of SWIFT included an Acoustic Doppler
342 Velocimeter (ADV) sampling at a single bin in the middle of the Aquadopp HR profile.

343 Figure 6 shows example burst data with mild breaking at short fetch and strong breaking
344 at long fetch (left versus right panels). The surface elevation ($z = 0$) appears constant in
345 the lower panels because the SWIFT is following the free-surface. The scatter for velocity
346 measurements is similar above and below the chosen correlation cutoff $c > 50$, as is the agree-
347 ment between the profile data and the extended velocity range (EVR) data (upper panels of
348 Figure 6). The depth profiles do not show any strong trends (lower panels of Figure 6).
349 In particular, the profiles of amplitude and correlation do not show any sharp features that
350 would indicate interference from surface reflections. The amplitude increases slightly near
351 the surface, possibly consistent with bubble injection by wave breaking (whitecaps).

352 Figure 7 shows examples of the spectra estimated during mild breaking and during strong
353 breaking (left versus right panels). The SWIFT orientation spectra show a trend of more
354 variance at lower frequencies, with broad response coinciding with the peak waves (upper
355 panels of Figure 7). The wave spectra from the SWIFT GPS show wind-waves at $f = 0.3$ Hz
356 (middle panels of Figure 7), consistent with nearby Waverider measurements. The SWIFT

357 pressure spectra show an expected peak at a natural frequency of $f_n \approx 0.7$ Hz and no
 358 peak at wave frequencies, consistent with surface following motion (middle panels of Figure
 359 7). The turbulent velocity spectra of a selected depth $z = 0.16$ m below the surface do
 360 show a peak at the natural frequency of the SWIFT, indicating the potential for motion
 361 contamination. However, two selected velocity differences (between depths $[z, z + 0.04\text{m}]$
 362 and $[z, z + 0.16\text{m}]$) do not show contamination peaks (lower panels of Figure 7). Moreover,
 363 the velocity difference spectra show an expected increase in energy density between smaller
 364 ($z, z + 0.04\text{m}$) and larger ($z, z + 0.16\text{m}$) lag distances. It is these velocity differences that
 365 determine the structure function $D(z, r)$ and associated dissipation rates (Eqs. 2-4).

366 Figure 8 shows examples of the processing of turbulent velocity profiles during mild and
 367 strong breaking (left versus right panels). The structure function $D(z, r)$ is fit to $Ar^{2/3}$
 368 at different depths z , and the slope A increases during stronger breaking (middle panels of
 369 Figure 8). The noise intercept N is small for all fits, and the RMSE error between the fits and
 370 the structure function is small. The resulting dissipation rate profiles $\bar{\epsilon}(z)$ are well-resolved
 371 and decrease away from the surface (lower panels of Figure 8). The estimates from the ADV
 372 at $z = 0.25$ m are consistent with structure function estimates at the same depth below
 373 the wave-following surface (although it must be noted that the largest values of $\bar{\epsilon}(z)$ are all
 374 closer to the surface and thus not evaluated by the ADV comparison). The depth-integrated
 375 dissipation rate \bar{E} during strong breaking (farther along the fetch) is approximately 2.5 times
 376 larger than during mild breaking (at short fetch).

377 Figure 9 shows the aggregated results of all SWIFT bursts on 12 November 2011, plotted
 378 as a function of north-south fetch distance x along Lake Washington. Wave heights, as
 379 estimated from the SWIFT GPS spectra, increase along the fetch from 0.2 m to 0.9 (upper
 380 panel of Figure 9). The vertically integrated dissipation rate estimates \bar{E} increase along
 381 the fetch from 0.1 W/m² to 1.0 W/m² (upper-middle panel of 9). In contrast, the noise in
 382 the structure function fits does not increase along the fetch (lower-middle panel of Figure
 383 9), which suggests the noise is not correlated with the dissipation estimates, nor with the

384 SWIFT motions (both of which increase with fetch). The ADV estimates of dissipation at
385 $z = 0.25$ m are consistent with the profile estimates $\bar{\epsilon}(z)$ along most of the fetch (lower panel
386 of Figure 9).

387 5. Discussion

388 In this section the magnitude and depth dependence of the dissipation rates during field
389 testing are compared with literature values and simple models. Then, errors and uncer-
390 tainties in the dissipation rates are discussed, as well as sensitivity to the correlation cutoff
391 applied to the Doppler velocity measurements.

392 *a. Scaling of dissipation rates*

393 The dissipation rate profiles observed at both the Duck FRF (surf breaking) and on Lake
394 WA (whitecap breaking) decrease with depth beneath the free surface (i.e., lower panels of
395 Figures 4 & 8). In the absence of wave breaking (i.e., offshore of the surf zone at the Duck
396 FRF or at very short fetch on Lake WA), the linear decrease is qualitatively consistent with
397 the well-known wall-layer dependence $\bar{\epsilon}(z) = u_*^3/(\kappa_v z)$, where u_* is the friction velocity and
398 κ_v is the von Karman constant, as shown by (Agrawal et al. 1992). During breaking, the
399 decrease in dissipation rate with depth is consistent with conceptual models for a source
400 of turbulence that diffuses beneath the surface (e.g., Craig and Banner (1994)). At the
401 Duck FRF, the depth dependence is weak, suggesting that diffusion is strong. On Lake WA,
402 the depth dependence is stronger and suggests that wave-breaking turbulence is isolated to
403 within 0.2 m of the surface, consistent with previous observations that whitecap turbulence
404 is largely contained to a depth less than the wave height (Terray et al. 1996; Gemmrich
405 2010). This depth scaling will be evaluated further in a future paper, including comparisons
406 with models for the direct injection of wave-breaking turbulence (as opposed to diffusion).

407 The ‘total’ dissipation rates observed at the Duck FRF can be compared to a simple

408 energy budget for the incoming swell. Requiring the energy flux per crest length, $F =$
 409 $\rho_w g \sqrt{gh} \int S_{\eta\eta}(f) df$, to be dissipated through a surf zone of cross-shore width x_{sz} , the average
 410 dissipation rate per unit surface area is F/x_{sz} (Mei 1989). Using the wave conditions observed
 411 at the FRF Aquadopp in $h = 3$ m water depth and $x_{sz} \approx 50$, the expected average dissipation
 412 is 50 W/m^2 . This value far exceeds the average ‘total’ dissipation obtained from the SWIFT
 413 within the surf zone ($\bar{E} \sim 0.2 \text{ W/m}^2$). Previous studies also have estimated surf zone
 414 dissipation rates much less than the expected energy flux gradient (Trowbridge and Elgar
 415 2001; Bryan et al. 2003; Feddersen 2011). Here, some of the difference may be explained by
 416 dissipation occurring below $z = 0.5$ m, especially near the seabed where Feddersen (2011)
 417 finds local dissipation rates in a saturated surf zone as high as 3 W/m^3 (i.e., similar order
 418 of magnitude to the near-surface SWIFT values in the Duck FRF surf zone). In addition,
 419 during this neap tide and mild waves, many waves did not break until reaching the steep
 420 foreshore ($x < 100$ m in Figure ??), where they are not captured by SWIFT measurements
 421 and where wave reflection may account for up to 30% of the incident swell energy flux
 422 (Elgar et al. 1994). Finally, energy flux also may be lost to mean currents (longshore and
 423 cross-shore) in the surf zone.

424 Another significant bias of the SWIFT surf-zone values may be the five-minute burst
 425 averaging, since the dissipation rates in the surf zone are event driven and unlikely to be
 426 normally distributed. Alternate averaging (e.g., log-normal) in Eq. 2 produces similar results
 427 for these field tests, suggesting the intermittence cannot be simply treated. The breakpoint
 428 of an irregular wave field on a natural beach is not well-defined; some waves may break
 429 further shoreward and some may break further seaward. Thus, even for a five-minute burst
 430 when the SWIFT is drifting within 10 m (cross-shore distance) of the nominal breakpoint,
 431 breaking (and presumably maximum dissipation) may only be observed for a few waves.
 432 This demonstrates the need for fixed instruments (Eulerian measurements) to interpret the
 433 SWIFT estimates. The surf-zone energy balance will be evaluated further in a future paper.

434 The ‘total’ dissipation rates observed on Lake WA can be compared to a simple energy

435 budget for wind forcing. Under equilibrium conditions (i.e., steady state fetch-limited wave
 436 field), the wind input rate W equals the ‘total’ dissipation rate \bar{E} . Since whitecapping is
 437 more regular, with uniform breaking rates of 1-2 per minute in a strongly forced sea state, the
 438 five-minute burst average \bar{E} from SWIFT methods is better suited to this cases (compared
 439 with intermittence in the surf-zone). Locally generated wind waves are forced by a wind
 440 stress $\tau = \rho_a C_D U_{10}^2$, where ρ_a is the density of air, U_{10} is the wind speed at a reference
 441 height of 10 m, and C_D is a drag coefficient that depends on wave age and wind speed
 442 (Donelan et al. 1993). The rate of energy input to the waves is estimated as a continuous
 443 stress acting on a surface moving at an effective speed c_e , such that (Gemmrich et al. 1994;
 444 Terray et al. 1996) $W = c_e \tau = c_e \rho_a C_D U_{10}^2$, where W is that rate of energy input per area of
 445 the sea surface, and the phase speed of the peak waves c_p is used for c_e . For the Lake WA
 446 tests, the wind input is approximately $W \sim 2 \text{ W/m}^2$, which is similar to the $\bar{E} \sim 1 \text{ W/m}^2$
 447 obtained from the SWIFT measurements. These energy balances will be evaluated further
 448 in a future paper, including alternatives to the $W = c_e \tau = c_p \tau$ assumption.

449 Finally, it must be noted that there are many sources of turbulent dissipation at the
 450 air-sea interface. The SWIFT-based estimates are the ‘total’ dissipation rate in the upper
 451 0.5 m of the ocean, and the above energy budgets attribute all of this dissipation to breaking
 452 waves. To successfully isolate the breaking contribution, it may be necessary to remove a
 453 non-breaking offset, which is estimated a priori, measured independently, or assumed to be
 454 the lowest value in the profile.

455 *b. Errors and uncertainty in dissipation rates*

456 There are three inter-related potential sources of error in the dissipation estimates: 1)
 457 errors introduced by SWIFT motion, 2) errors in the fit to the spatial structure of an assumed
 458 turbulence cascade, and 3) errors in the pulse-coherent Doppler velocity measurements.

459 Motion contamination is quantified using frequency spectra. There are no observed
 460 spectral peaks in the difference between velocity bins, although there are SWIFT motion

461 peaks for individual velocity bins (see Figures 3 & 7). Thus, the structure function (Eq. 2)
 462 is unlikely to be contaminated by wave or platform motions.

463 Errors in the fit to an assumed eddy cascade are quantified by an uncertainty $\sigma_{\epsilon\pm}$, the
 464 propagated RMSE of the fit, and by N , the noise intercept of the fit. In general, $\sigma_{\epsilon\pm} \ll \bar{\epsilon}$
 465 (see uncertainty bars in lower panels of Figures 4 & 8) and $N \ll A(z)r^{2/3}$ (see intercepts
 466 in middle panels of Figures 4 & 8). More importantly, these values are uncorrelated with
 467 changes in wave conditions (see lower panels of Figures 5 & 9).

468 Errors from the pulse-coherent Doppler velocity measurements are more difficult to quan-
 469 tify, although they are implicit to the values of $\sigma_{\epsilon\pm}$ and N discussed above. A threshold
 470 for pulse correlation commonly is used to remove spurious points (e.g., Rusello (2009); Fed-
 471 dersen (2010)), and the choice of $c > 50$ (out of 100) is evaluated relative to the implicit
 472 error N . Figures 10 & 11 shows the distribution of N over all bursts and all vertical bins for
 473 four different values of correlation cutoffs. Also shown are vertical lines with the expected
 474 range $-2\sigma_u^2 < N < 2\sigma_u^2$ given a Doppler velocity uncertainty of $\sigma_u = 0.025$ m/s, or 5% of
 475 the along-beam velocity range. The noise intercept N tends to be normally distributed for a
 476 given depth z , as expected for ‘white noise’. There is a trend towards narrower distributions
 477 with higher correlation cutoffs, although there are notable differences between the two field
 478 tests.

479 For the Duck FRF tests (Figure 10), the overall effect of the correlation threshold on noise
 480 N distributions is minimal, and noise intercepts are generally within the $\pm 2\sigma^2$ range. This is
 481 in contrast to the substantial quality control applied in the burst examples (e.g., Figure 2),
 482 however it must be noted that full quality control includes an amplitude threshold $a > 30$
 483 which removes points in air (that also have low correlations). There is a trend towards larger
 484 N values for deeper z locations. These locations have fewer points in the fit, owing to the
 485 one-sided (i.e., downwards) differencing in the structure function calculation (Eq. 2), and
 486 are controlled by small r values. The trend in N thus may be related to the triangular bin
 487 weighting used in Nortek’s processing, which results in some overlap in velocity information

488 between neighboring bins (i.e., at $r = 0.04$ m).

489 For the Lake WA tests (Figure 11), the overall effect of the correlation threshold on noise
490 N distributions is more significant, and consistent normal distributions at all depths are only
491 observed for $c > 50$ and $c > 75$. This suggests that the correlation cutoff $c > 50$ is important
492 for obtaining robust $\bar{\epsilon}(z)$ estimates. The noise intercepts N are generally more negative,
493 compared with the Duck FRF tests, and are centered at the edge of the $-2\sigma^2$ range. The
494 more negative N values on Lake WA may be the result of peak waves ($f_p = 0.33$ Hz) that
495 are closer to the natural frequency of the SWIFT ($f_n = 0.7$ Hz) and may cause increased
496 motion contamination relative to the peak waves during the Duck FRF testing ($f_p = 0.1$
497 Hz).

498 Although there is no known parametric dependence or clear empirical value, it is evident
499 from the burst examples (Figures 2 & 6) and full data sets (Figures 10 & 11) that a higher
500 correlation cutoff improves the quality of the dissipation rate estimates, at least within the
501 constraint of removing too many points to obtain robust statistics. Testing selected values
502 suggests that $c > 50$ is reasonable cutoff. For the SWIFT measurements, evaluation of the
503 pulse correlations may be more important in assessing the potential for surface reflections
504 than in quality controlling individual points. Restated, a random distribution of low correla-
505 tions will have a minimal effect on the determination of dissipation rates, but a concentration
506 of low correlations at particular depth indicates acoustic contamination via surface reflection
507 that may severely deteriorate the quality of dissipation estimates using a structure function
508 method.

509 Finally, the noise intercepts and uncertainties provide guidance on the minimum values
510 of dissipation that may be obtained from the SWIFT observations. Using the $\sigma = 0.025$
511 m/s value, the minimum dissipation rate for $N < Ar^{2/3}$ is $\bar{\epsilon}_{min} = 0.0372$ W/m³[= $3.7 \times$
512 10^{-5} Kg/m³]. The minimum depth integrated dissipation rate is then $\bar{E}_{min} = 0.0238$ W/m².
513 These minima are admittedly large in general oceanographic terms, however they are at
514 least an order of magnitude smaller than any of the results during field tests (or any of the

515 magnitudes estimated from simple analytic energy budgets). In addition, these minima are
516 smaller than the typical uncertainties $\sigma_{\epsilon\pm} \sim 0.1 \text{ W/m}^3$ and $\sigma_{E\pm} \sim 0.05 \text{ W/m}^2$. Clearly,
517 future application of SWIFT-based dissipation rates must be careful to only evaluate results
518 well above these minima and well above the respective uncertainty values.

519 **6. Conclusion**

520 A new wave-following platform, termed the Surface Wave Instrument Float with Tracking
521 (SWIFT), is used to estimate the dissipation rate of turbulent kinetic energy within the
522 upper half-meter of the ocean. Motion data are used to estimate the wave conditions and to
523 evaluate the degree of motion contamination. Pulse-coherent Doppler velocity data are used
524 to determine the spatial structure of the near-surface turbulence and thereby estimate burst-
525 averaged dissipation rates as a function of depth and time. The approach is demonstrated
526 in two field tests under markedly different conditions (shallow-water surf breaking versus
527 deep water whitecap breaking). In both cases, motion contamination is small and error
528 propagation indicates robust estimates of dissipation. The advantages of the wave-following
529 reference frame, in particular observations above the still water level and along a spatial
530 gradient (e.g., depth or fetch), are evident in the field tests.

531 *Acknowledgments.*

532 Thanks to APL-UW Field Engineers J. Talbert and A. deKlerk for tireless efforts in
533 the design, assembling, testing, deployment, and recovery of the SWIFTs. Thanks to the
534 US-ACE Field Research Facility (FRF) staff J. Hanson and K. Hathaway for excellent logis-
535 tical support, array data, and bathymetry surveys. Thanks to C. Chickadel, D. Clark, M.
536 Haller, D. Honegger, A. Jessup, E. Williams and G. Wilson for daily shore support during
537 FRF tests and to M. Schwendeman for help with Lake Washington tests. Thanks to F.

617 List of Figures

- 618 1 (a) Dimensional drawing and (b) picture of a SWIFT: Surface Wave Instru-
619 ment Float with Tracking. Drawing courtesy of J. Talbert, APL-UW. 33
- 620 2 Example raw SWIFT burst data collected in shallow water at the Duck FRF.
621 The left panels show non-breaking conditions outside of the surf zone, and
622 the right panels show breaking conditions within the surf zone. Conditions
623 are determined by GPS location, and by the onboard video images shown in
624 the upper panels. Velocity data quality control, using pulse-pulse correlation
625 and extended velocity range, is shown in the middle panels. The lower panels
626 show the resulting profiles of turbulent velocity $u'(z)$, correlation $c(z)$, and
627 backscatter amplitude $a(z)$. Thick lines are mean values and dashed lines are
628 \pm one standard deviation. 34
- 629 3 Example SWIFT spectra collected in shallow water at the Duck FRF. The
630 left panels show non-breaking conditions outside of the surf zone, and the
631 right panels show breaking conditions within the surf zone. Conditions are
632 determined by GPS location, and by the onboard video images shown in the
633 upper panels. Middle panels show wave height spectra (from independent
634 FRF measurements) and SWIFT platform motion spectra (pitch, roll, head-
635 ing, and pressure from the SWIFT Aquadopp HR data). Lower panels show
636 velocity spectra, including wave orbital motion (from independent FRF mea-
637 surements) and turbulence at one selected depth (from the SWIFT Aquadopp
638 HR data). Also shown are spectra of differences between select depths of the
639 turbulence profile, which is the relevant quantity for calculating the structure
640 function. 35

- 641 4 Example SWIFT burst results collected in shallow water at the Duck FRF.
642 The left panels show non-breaking conditions outside of the surf zone, and the
643 right panels show breaking conditions within the surf zone. Conditions are
644 determined by GPS location, and by the onboard video images shown in the
645 upper panels. The middle panels show the structure function $D(z, r)$ (Eq. 2)
646 and associated fits $Ar^{2/3} + N$ (Eq. 3) as dots and lines, respectively. Colors
647 indicate depth beneath the wave following surface. The lower panels show
648 the resulting depth profiles of dissipation rate $\bar{\epsilon}(z)$, with horizontal bars for
649 uncertainties $\sigma_{\epsilon\pm}$. 36
- 650 5 Aggregated results of SWIFT drifts at the Duck FRF versus cross-shore po-
651 sition. Upper panel shows the nearshore bathymetry as a shaded region and
652 the still water level as a dashed line. Middle panel shows the depth-integrated
653 dissipation \bar{E} , which increases shoreward (decreasing x). Vertical bars show
654 uncertainties $\sigma_{E\pm}$. Lower panel shows the noise intercepts N of the structure
655 function fit, which are approximately uniform at all cross-shore positions. Col-
656 ors indicate depth beneath the wave following surface, as in Figure 4. The
657 FRF instrument (bottom-mounted Aquadopp) used for wave spectra in Figure
658 3 is located at $x = 232$ m. 37
- 659 6 Example raw SWIFT burst data collected in deep water on Lake Washington.
660 The left panels show moderate-breaking conditions at a short fetch distance,
661 and the right panels show strong breaking conditions at a larger fetch distance.
662 Conditions are determined by GPS location, and by the onboard video images
663 shown in the upper panels. Velocity data quality control, using pulse-pulse
664 correlation and extended velocity range, is shown in the middle panels. The
665 lower panels show the resulting profiles of turbulent velocity $u'(z)$, correlation
666 $c(z)$, and backscatter amplitude $a(z)$. Thick lines are mean values and dashed
667 lines are \pm one standard deviation. 38

668 7 Example SWIFT burst spectra collected in deep water on Lake Washington.
669 The left panels show moderate-breaking conditions at a short fetch distance,
670 and the right panels show strong breaking conditions at a larger fetch dis-
671 tance. Conditions are determined by GPS location, and by the onboard video
672 images shown in the upper panels. Middle panels show wave height spectra
673 (from SWIFT GPS data) and SWIFT platform motion spectra (pitch, roll,
674 heading, and pressure from the SWIFT Aquadopp HR). Lower panels show
675 velocity spectra, including wave orbital motion (from SWIFT GPS data) and
676 turbulence at one selected depth (from the SWIFT Aquadopp HR data). Also
677 shown are spectra of differences between select depths of the turbulence pro-
678 file, which is the relevant quantity for calculating the structure function. 39

679 8 Example SWIFT burst results collected in deep water on Lake Washington.
680 The left panels show moderate-breaking conditions at a short fetch distance,
681 and the right panels show strong breaking conditions at a larger fetch distance.
682 Conditions are determined by GPS location, and by the onboard video images
683 shown in the upper panels. The middle panels show the structure function
684 $D(z, r)$ (Eq. 2) and associated fits $Ar^{2/3} + N$ (Eq. 3) as dots and lines,
685 respectively. Colors indicate depth beneath the wave following surface. The
686 lower panels show the resulting depth profiles of dissipation rate $\bar{\epsilon}(z)$, with
687 horizontal bars for uncertainties $\sigma_{\epsilon\pm}$. The corresponding ADV estimates at
688 $z = 0.25$ m are shown in green. 40

- 689 9 Aggregated results of SWIFT drifts on Lake WA versus fetch x . Upper panel
690 shows the significant wave height estimated from the SWIFT GPS spectra as
691 $H_s = 4\sqrt{\int S_{\eta\eta}(f)df}$. Upper-middle panel shows the depth-integrated dissipation
692 \bar{E} . Vertical bars show uncertainties $\sigma_{E\pm}$. Lower-middle panel shows the
693 noise intercepts N of the structure function fit, which are approximately uni-
694 form at all fetch. Colors indicate depth beneath the wave following surface, as
695 in Figure 8. Lower panel shows the comparison of dissipation rate $\bar{\epsilon}(z = 0.25$
696 m) obtained from the Aquadopp (AQD) structure function and the acoustic
697 Doppler velocimeter (ADV) spectra. 41
- 698 10 Distributions of noise intercepts N from all bursts at Duck FRF using four
699 different pulse correlation cutoffs for quality control of velocity data. Clock-
700 wise from upper-left: $c > 0, c > 25, c > 75, c > 50$. Colors indicate depth
701 beneath the wave following surface, as in Figure 4. Dashed lines indicate the
702 expected range for N , given a Doppler velocity uncertainty of $\sigma_u = 0.025$ m/s. 42
- 703 11 Distributions of noise intercepts N from all bursts on Lake WA using four dif-
704 ferent pulse correlation cutoffs for quality control of velocity data. Clockwise
705 from upper-left: $c > 0, c > 25, c > 75, c > 50$. Colors indicate depth beneath
706 the wave following surface, as in Figure 8. Dashed lines indicate the expected
707 range for N , given a Doppler velocity uncertainty of $\sigma_u = 0.025$ m/s. 43

Surface Wave Instrument Float w/ Tracking (SWIFT)

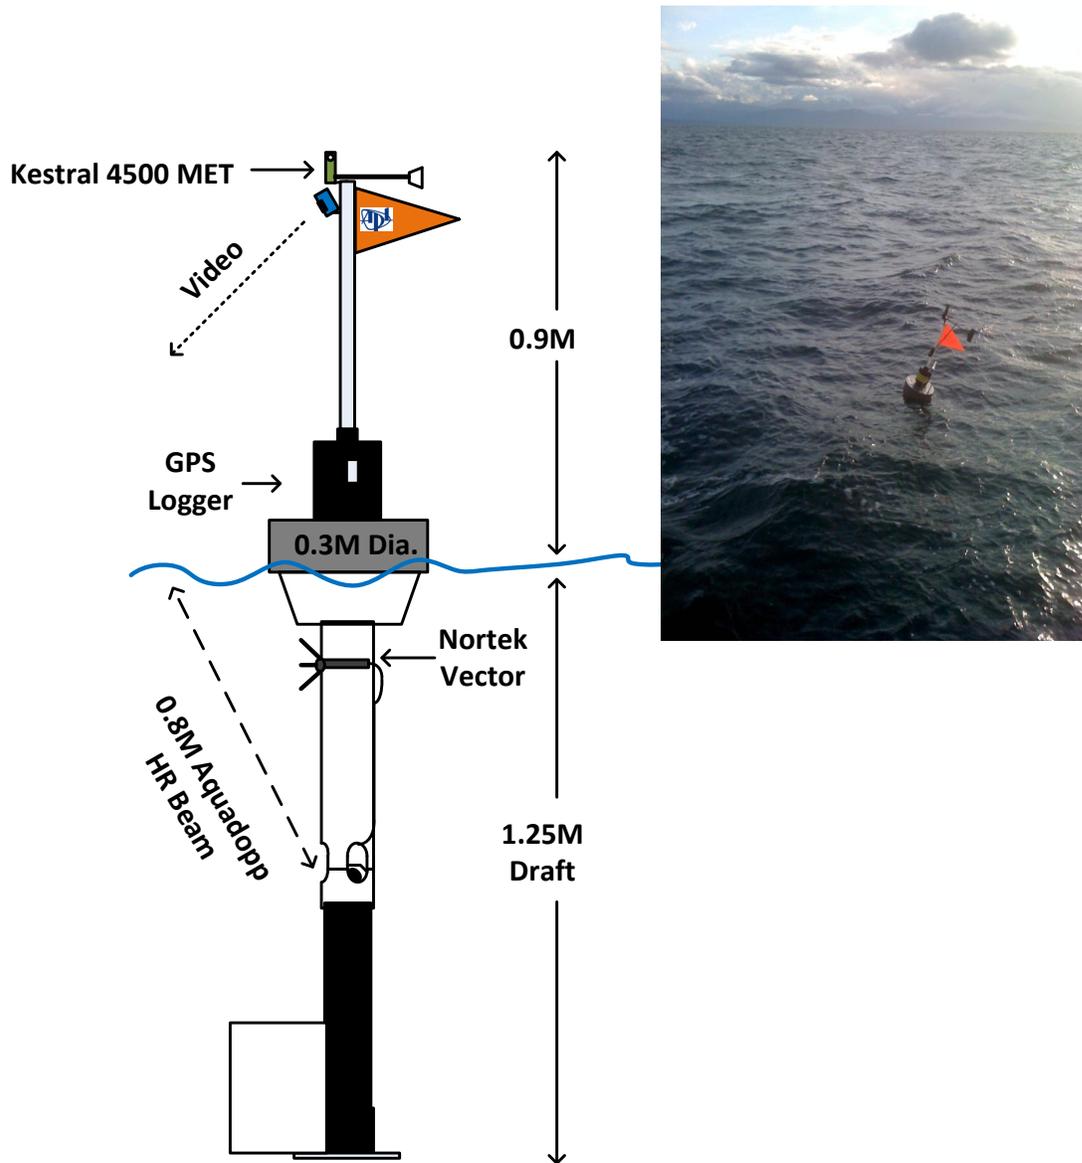

FIG. 1. (a) Dimensional drawing and (b) picture of a SWIFT: Surface Wave Instrument Float with Tracking. Drawing courtesy of J. Talbert, APL-UW.

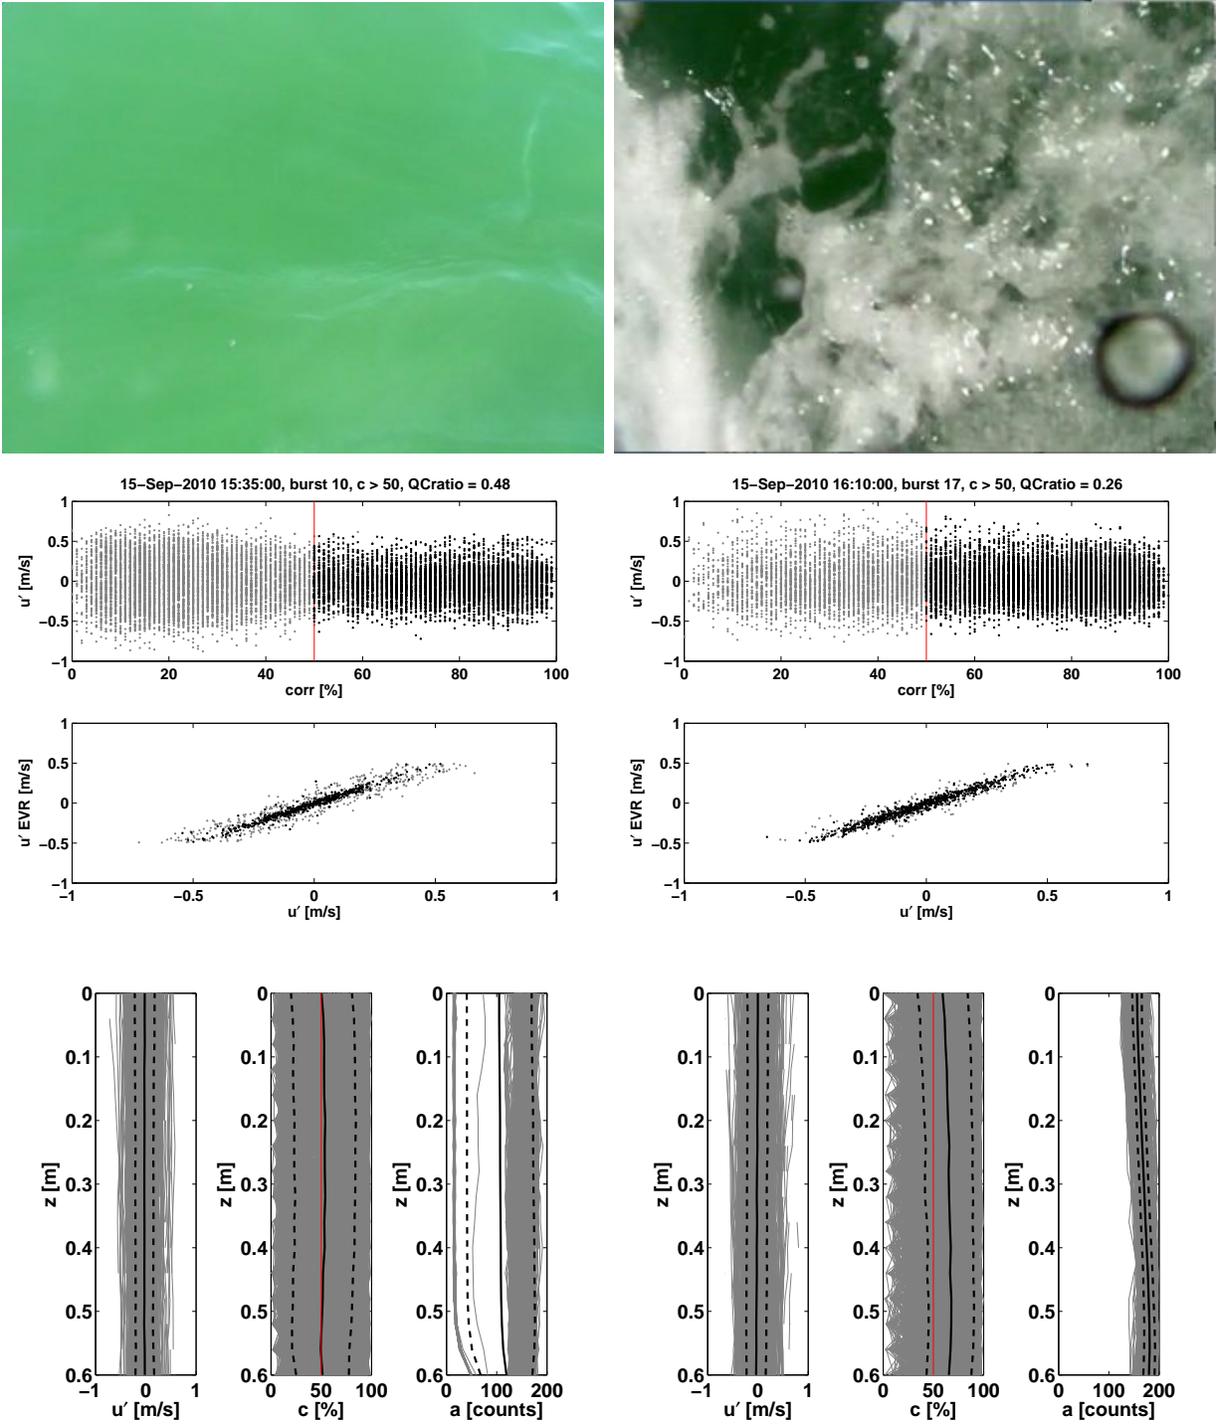

FIG. 2. Example raw SWIFT burst data collected in shallow water at the Duck FRF. The left panels show non-breaking conditions outside of the surf zone, and the right panels show breaking conditions within the surf zone. Conditions are determined by GPS location, and by the onboard video images shown in the upper panels. Velocity data quality control, using pulse-pulse correlation and extended velocity range, is shown in the middle panels. The lower panels show the resulting profiles of turbulent velocity $u'(z)$, correlation $c(z)$, and backscatter amplitude $a(z)$. Thick lines are mean values and dashed lines are \pm one standard deviation.

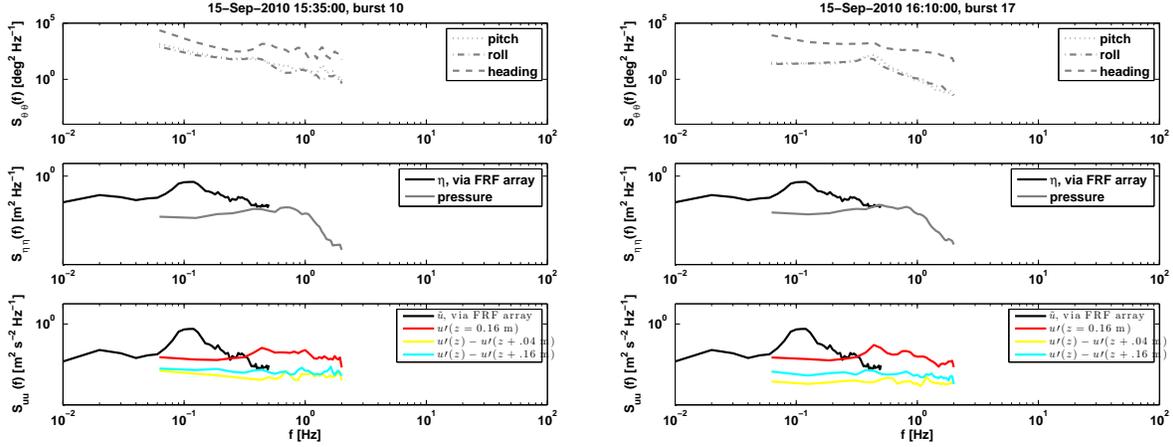

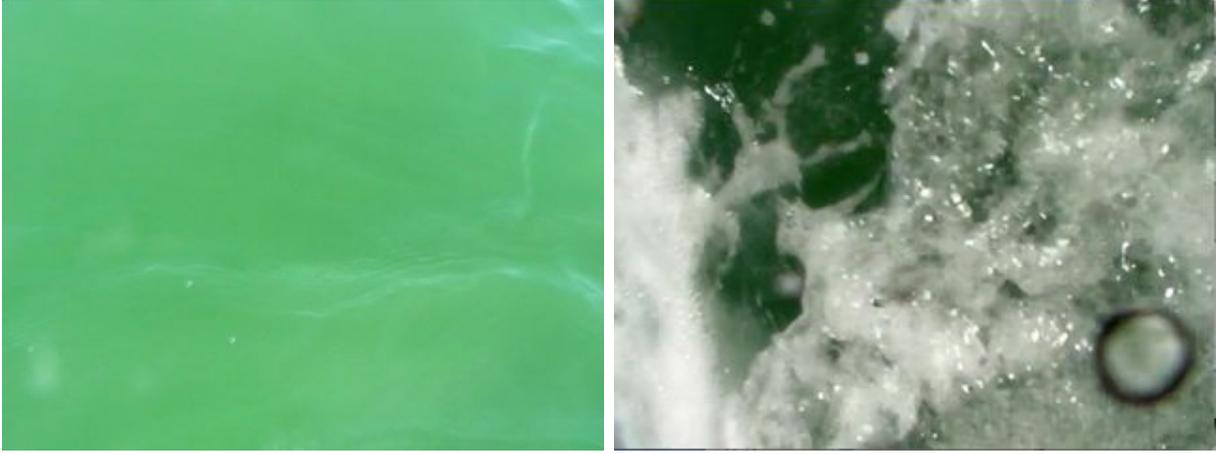

FIG. 3. Example SWIFT spectra collected in shallow water at the Duck FRF. The left panels show non-breaking conditions outside of the surf zone, and the right panels show breaking conditions within the surf zone. Conditions are determined by GPS location, and by the onboard video images shown in the upper panels. Middle panels show wave height spectra (from independent FRF measurements) and SWIFT platform motion spectra (pitch, roll, heading, and pressure from the SWIFT Aquadopp HR data). Lower panels show velocity spectra, including wave orbital motion (from independent FRF measurements) and turbulence at one selected depth (from the SWIFT Aquadopp HR data). Also shown are spectra of differences between select depths of the turbulence profile, which is the relevant quantity for calculating the structure function.

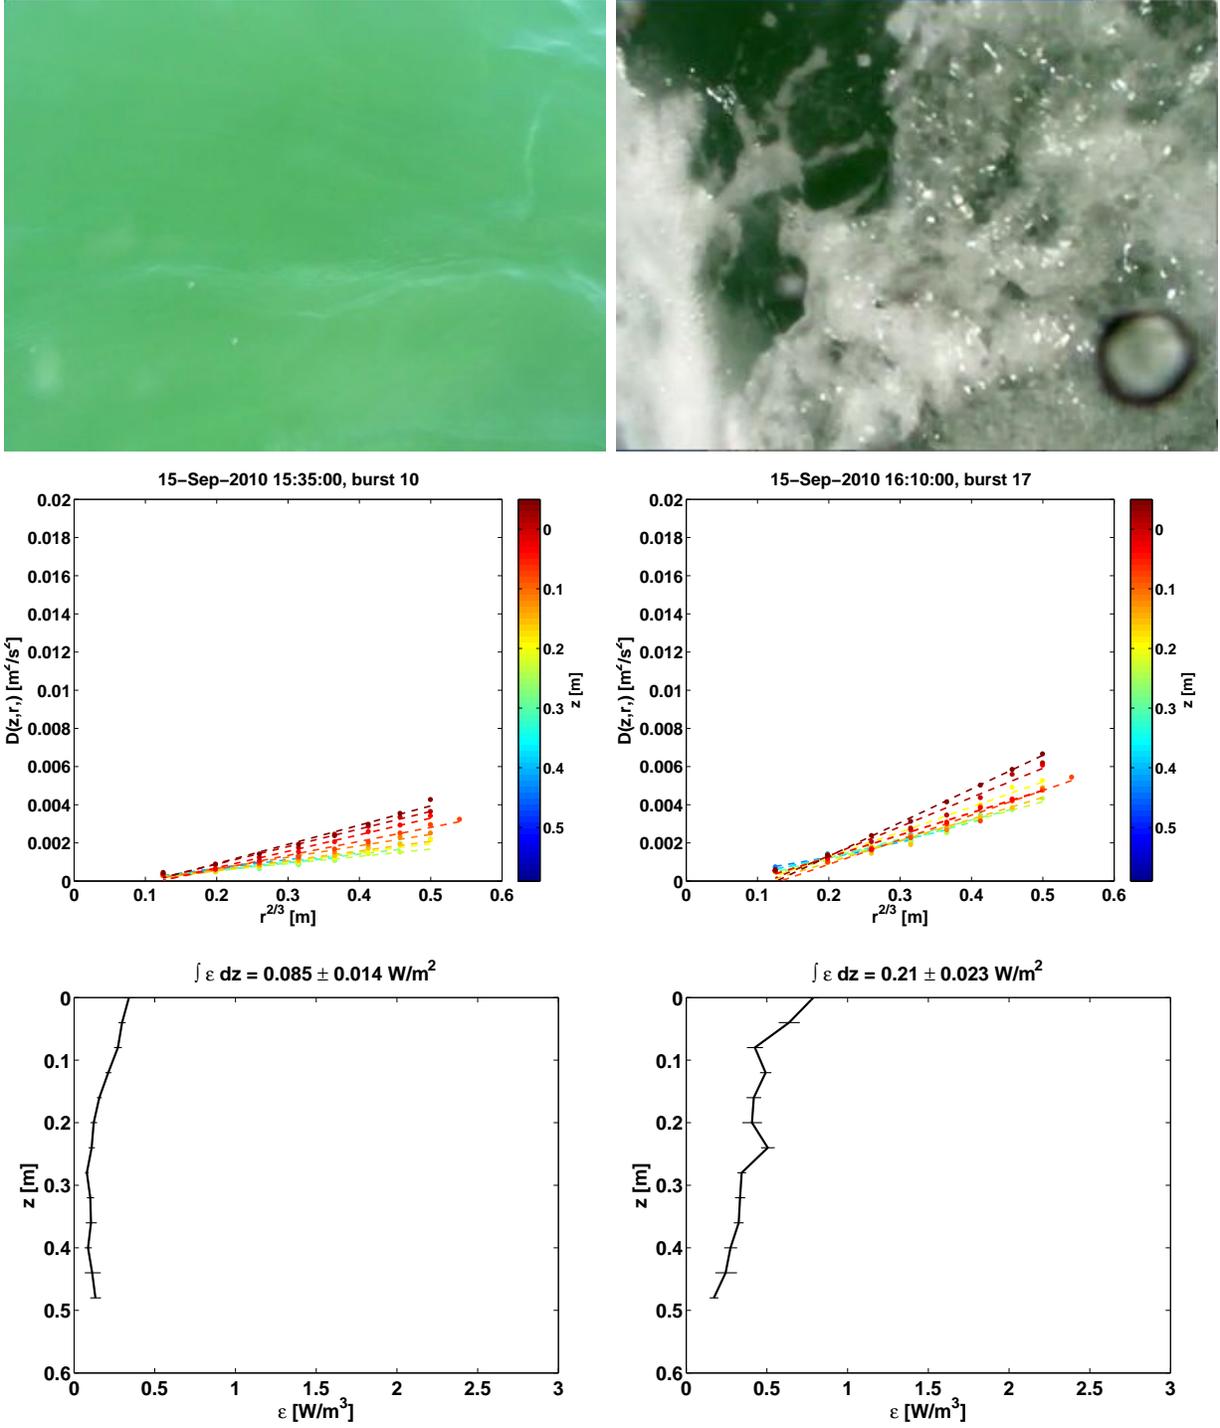

FIG. 4. Example SWIFT burst results collected in shallow water at the Duck FRF. The left panels show non-breaking conditions outside of the surf zone, and the right panels show breaking conditions within the surf zone. Conditions are determined by GPS location, and by the onboard video images shown in the upper panels. The middle panels show the structure function $D(z, r)$ (Eq. 2) and associated fits $Ar^{2/3} + N$ (Eq. 3) as dots and lines, respectively. Colors indicate depth beneath the wave following surface. The lower panels show the resulting depth profiles of dissipation rate $\bar{\epsilon}(z)$, with horizontal bars for uncertainties $\sigma_{\epsilon \pm}$.

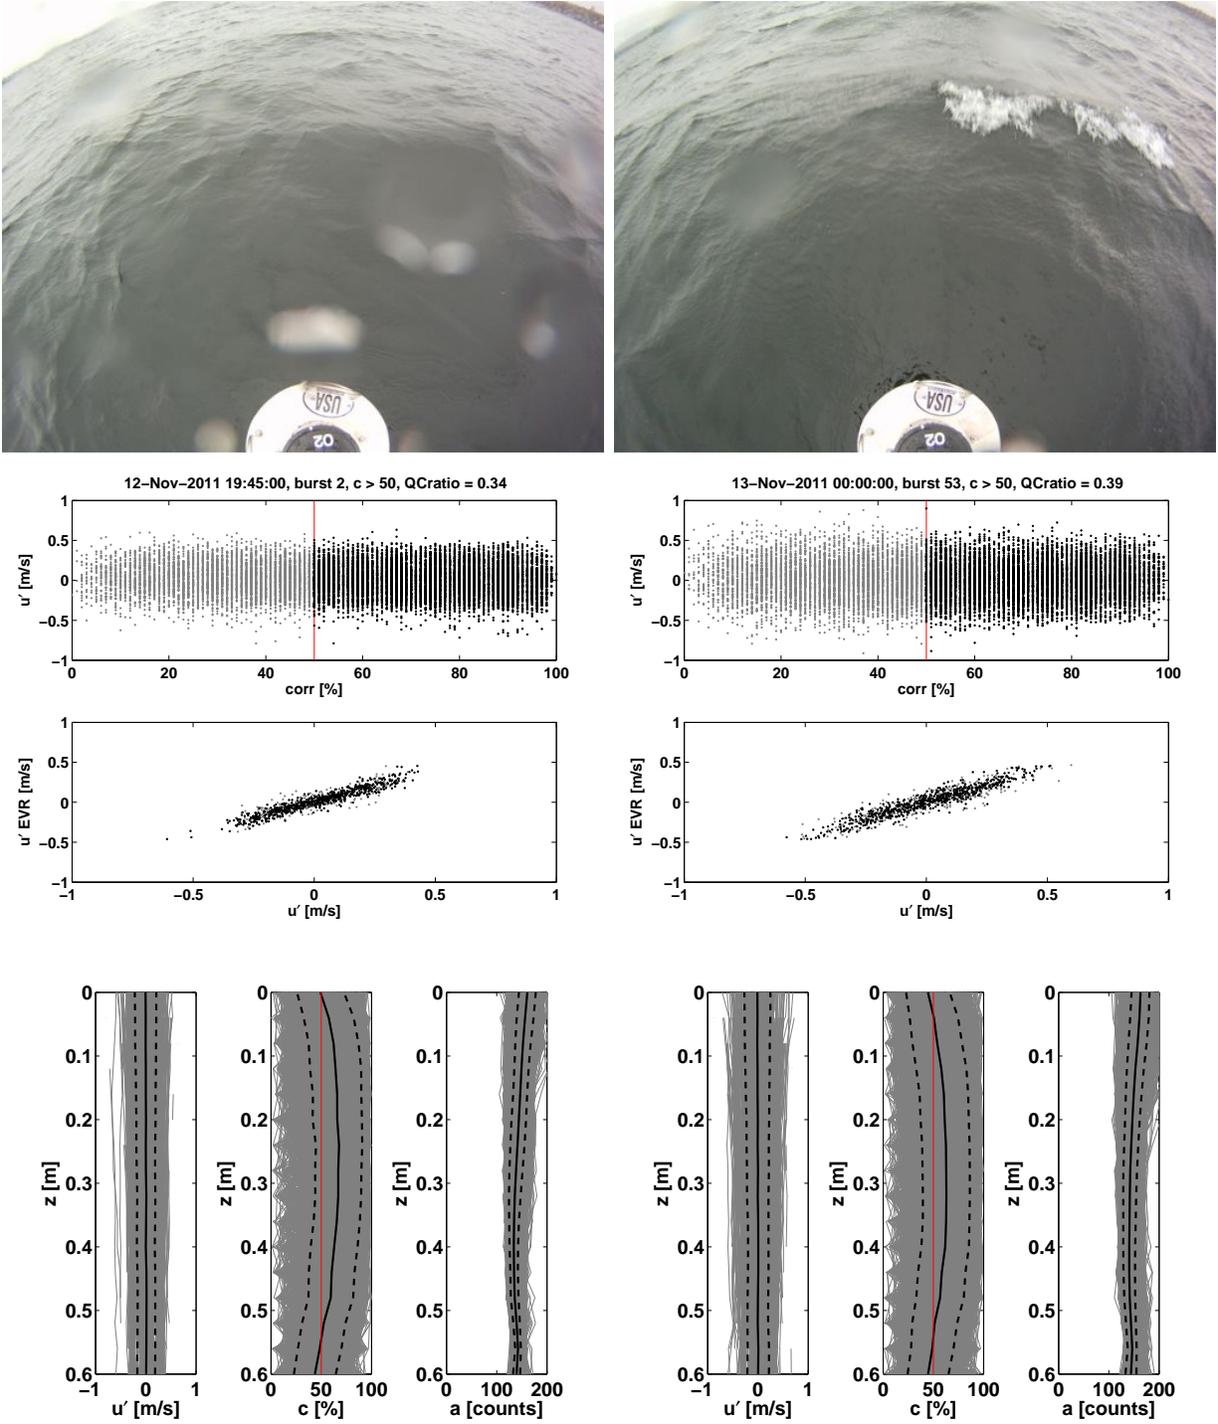

FIG. 6. Example raw SWIFT burst data collected in deep water on Lake Washington. The left panels show moderate-breaking conditions at a short fetch distance, and the right panels show strong breaking conditions at a larger fetch distance. Conditions are determined by GPS location, and by the onboard video images shown in the upper panels. Velocity data quality control, using pulse-pulse correlation and extended velocity range, is shown in the middle panels. The lower panels show the resulting profiles of turbulent velocity $u'(z)$, correlation $c(z)$, and backscatter amplitude $a(z)$. Thick lines are mean values and dashed lines are \pm one standard deviation. 38

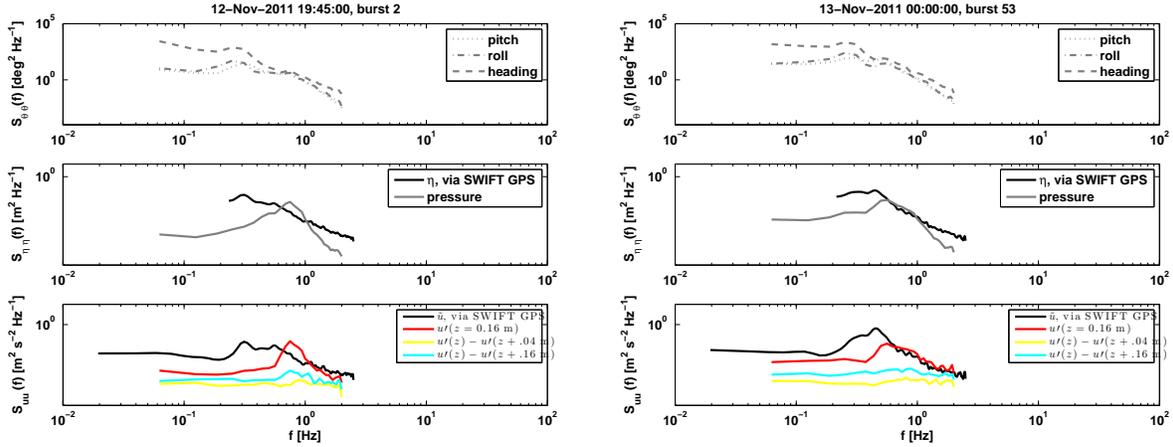

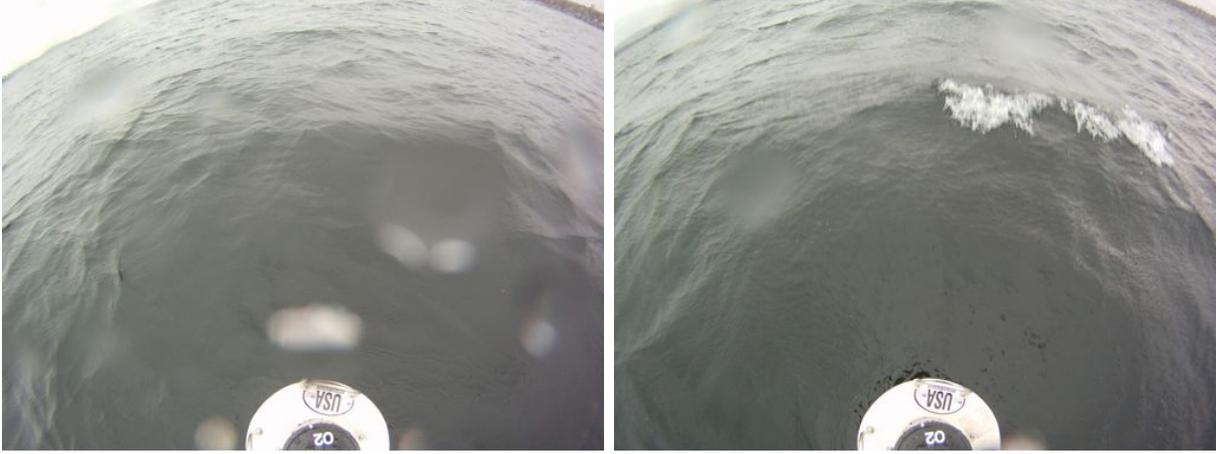

FIG. 7. Example SWIFT burst spectra collected in deep water on Lake Washington. The left panels show moderate-breaking conditions at a short fetch distance, and the right panels show strong breaking conditions at a larger fetch distance. Conditions are determined by GPS location, and by the onboard video images shown in the upper panels. Middle panels show wave height spectra (from SWIFT GPS data) and SWIFT platform motion spectra (pitch, roll, heading, and pressure from the SWIFT Aquadopp HR). Lower panels show velocity spectra, including wave orbital motion (from SWIFT GPS data) and turbulence at one selected depth (from the SWIFT Aquadopp HR data). Also shown are spectra of differences between select depths of the turbulence profile, which is the relevant quantity for calculating the structure function.

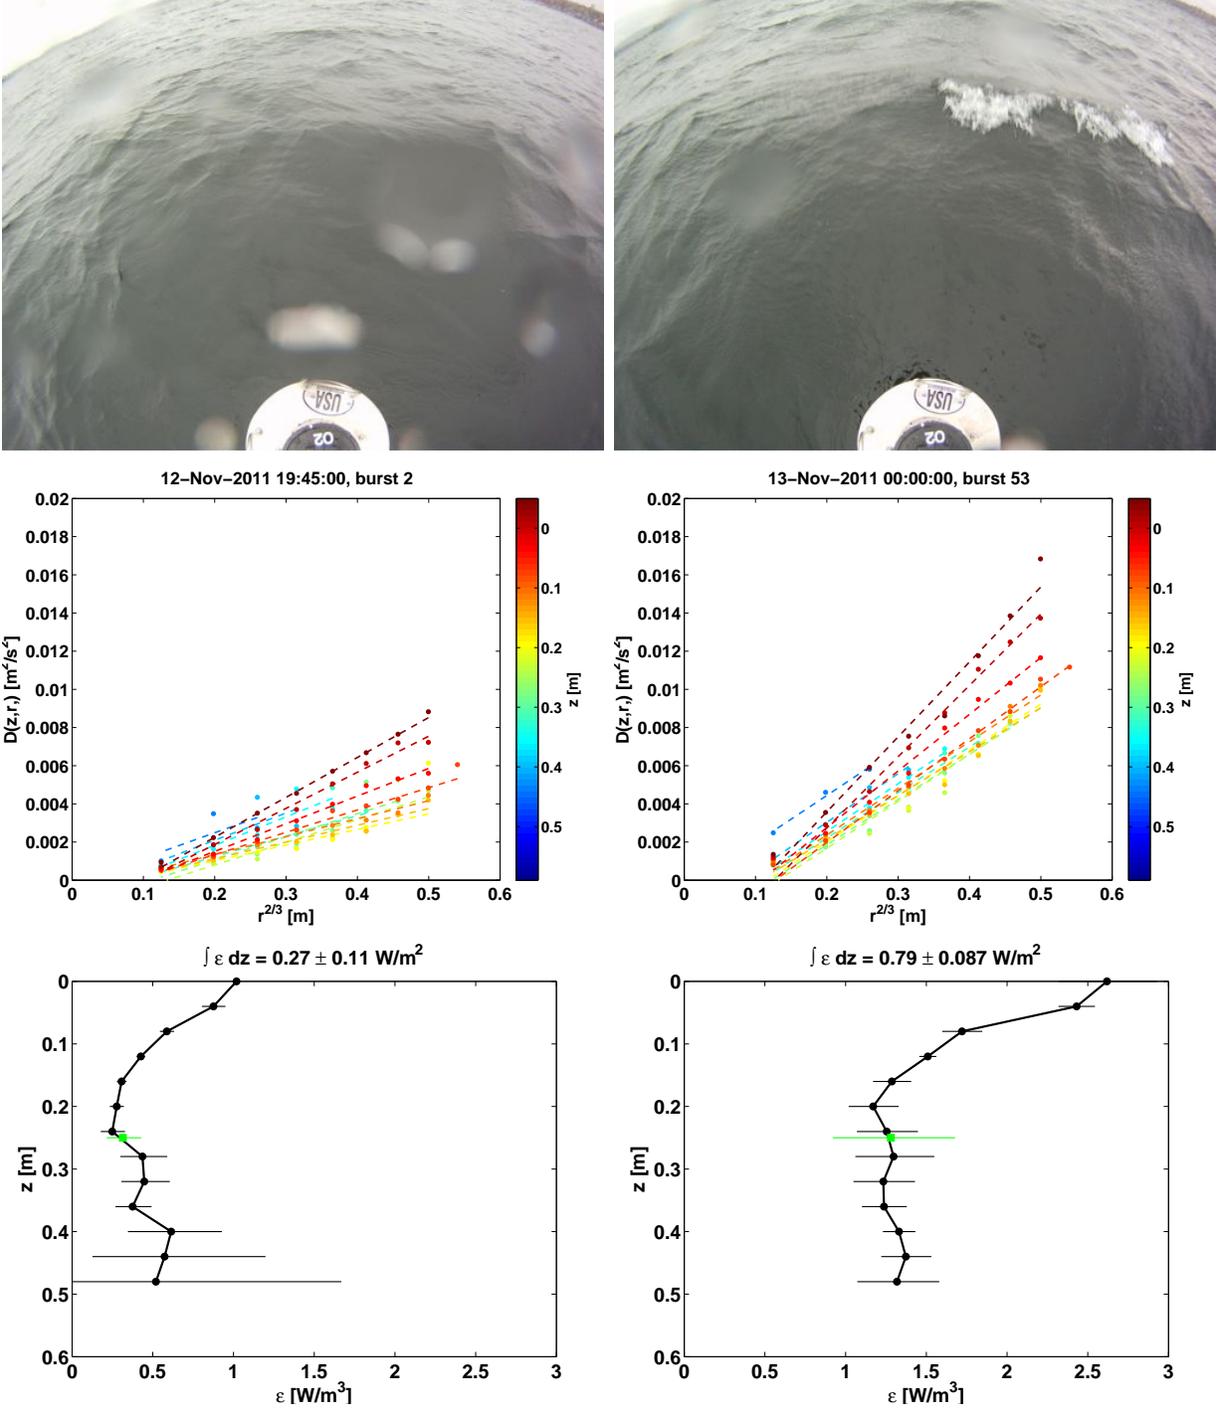

FIG. 8. Example SWIFT burst results collected in deep water on Lake Washington. The left panels show moderate-breaking conditions at a short fetch distance, and the right panels show strong breaking conditions at a larger fetch distance. Conditions are determined by GPS location, and by the onboard video images shown in the upper panels. The middle panels show the structure function $D(z,r)$ (Eq. 2) and associated fits $Ar^{2/3} + N$ (Eq. 3) as dots and lines, respectively. Colors indicate depth beneath the wave following surface. The lower panels show the resulting depth profiles of dissipation rate $\bar{\epsilon}(z)$, with horizontal bars for uncertainties $\sigma_{\epsilon\pm}$. The corresponding ADV estimates at $z = 0.25$ m are shown in green.

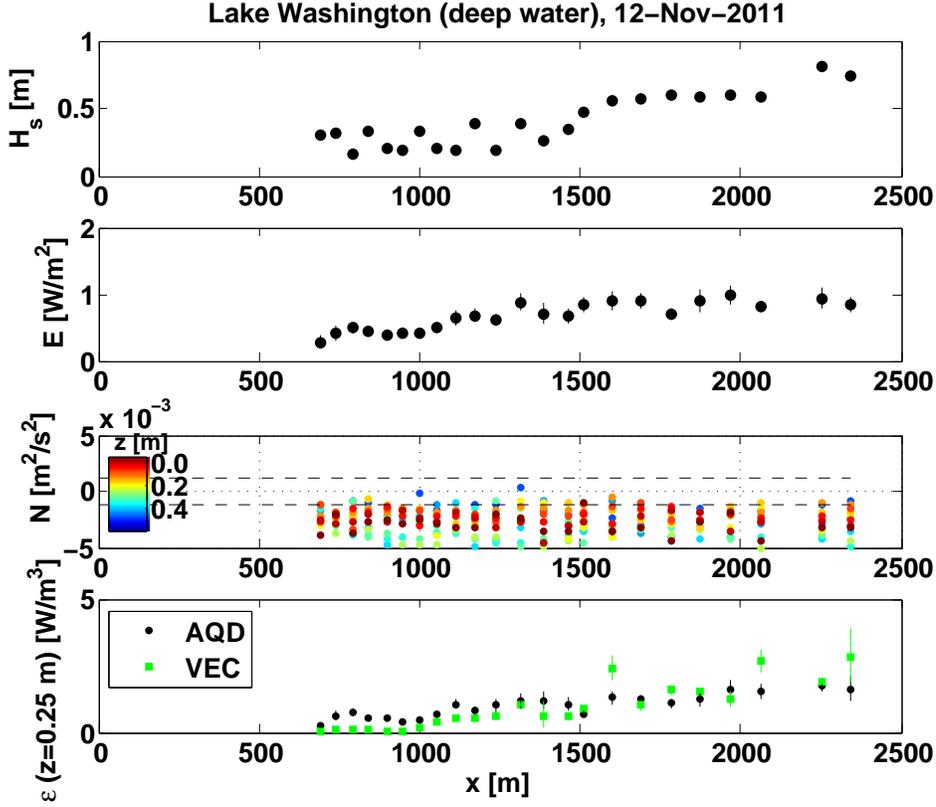

FIG. 9. Aggregated results of SWIFT drifts on Lake WA versus fetch x . Upper panel shows the significant wave height estimated from the SWIFT GPS spectra as $H_s = 4\sqrt{\int S_{\eta\eta}(f)df}$. Upper-middle panel shows the depth-integrated dissipation \bar{E} . Vertical bars show uncertainties $\sigma_{E\pm}$. Lower-middle panel shows the noise intercepts N of the structure function fit, which are approximately uniform at all fetch. Colors indicate depth beneath the wave following surface, as in Figure 8. Lower panel shows the comparison of dissipation rate $\bar{\varepsilon}(z = 0.25 \text{ m})$ obtained from the Aquadopp (AQD) structure function and the acoustic Doppler velocimeter (ADV) spectra.

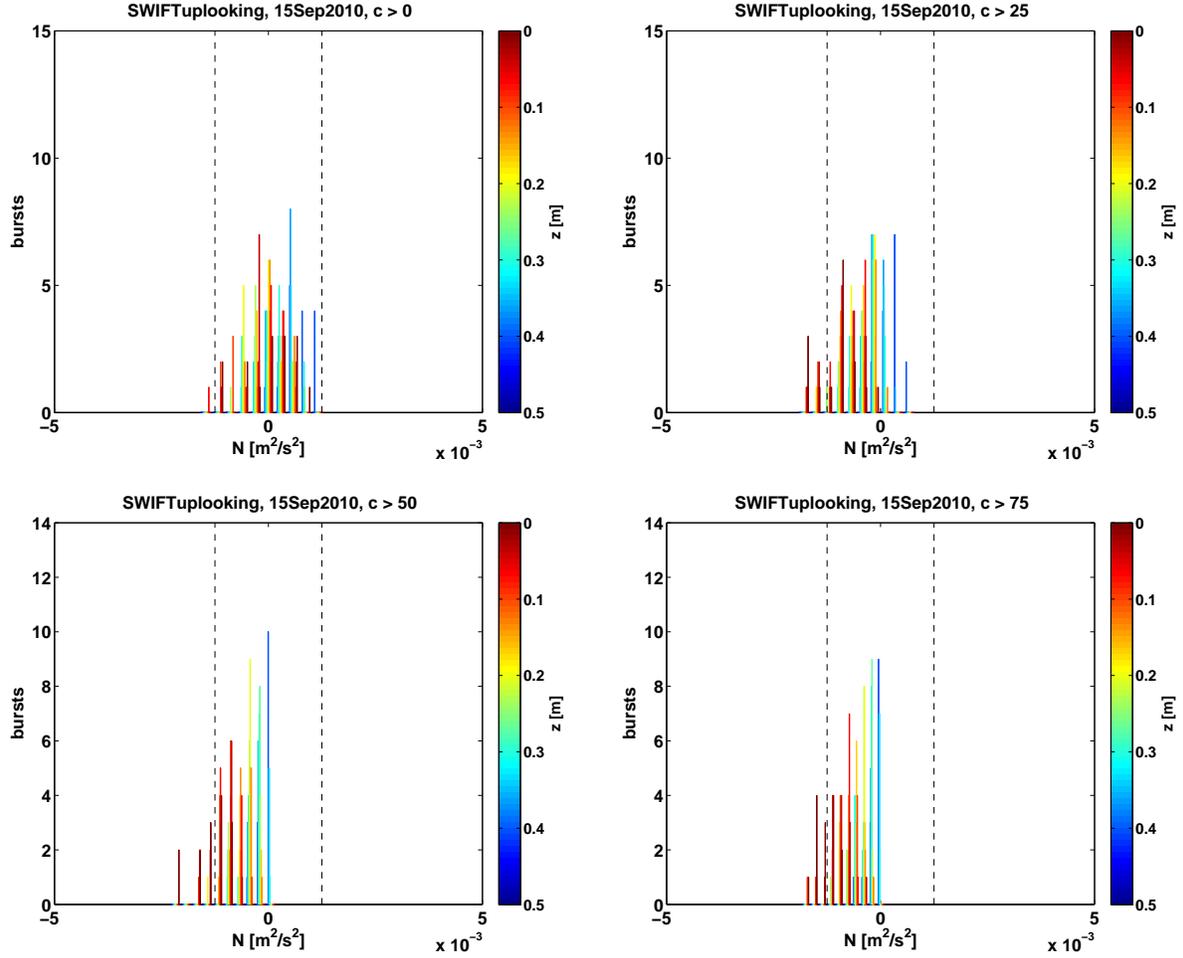

FIG. 10. Distributions of noise intercepts N from all bursts at Duck FRF using four different pulse correlation cutoffs for quality control of velocity data. Clockwise from upper-left: $c > 0, c > 25, c > 75, c > 50$. Colors indicate depth beneath the wave following surface, as in Figure 4. Dashed lines indicate the expected range for N , given a Doppler velocity uncertainty of $\sigma_u = 0.025$ m/s.

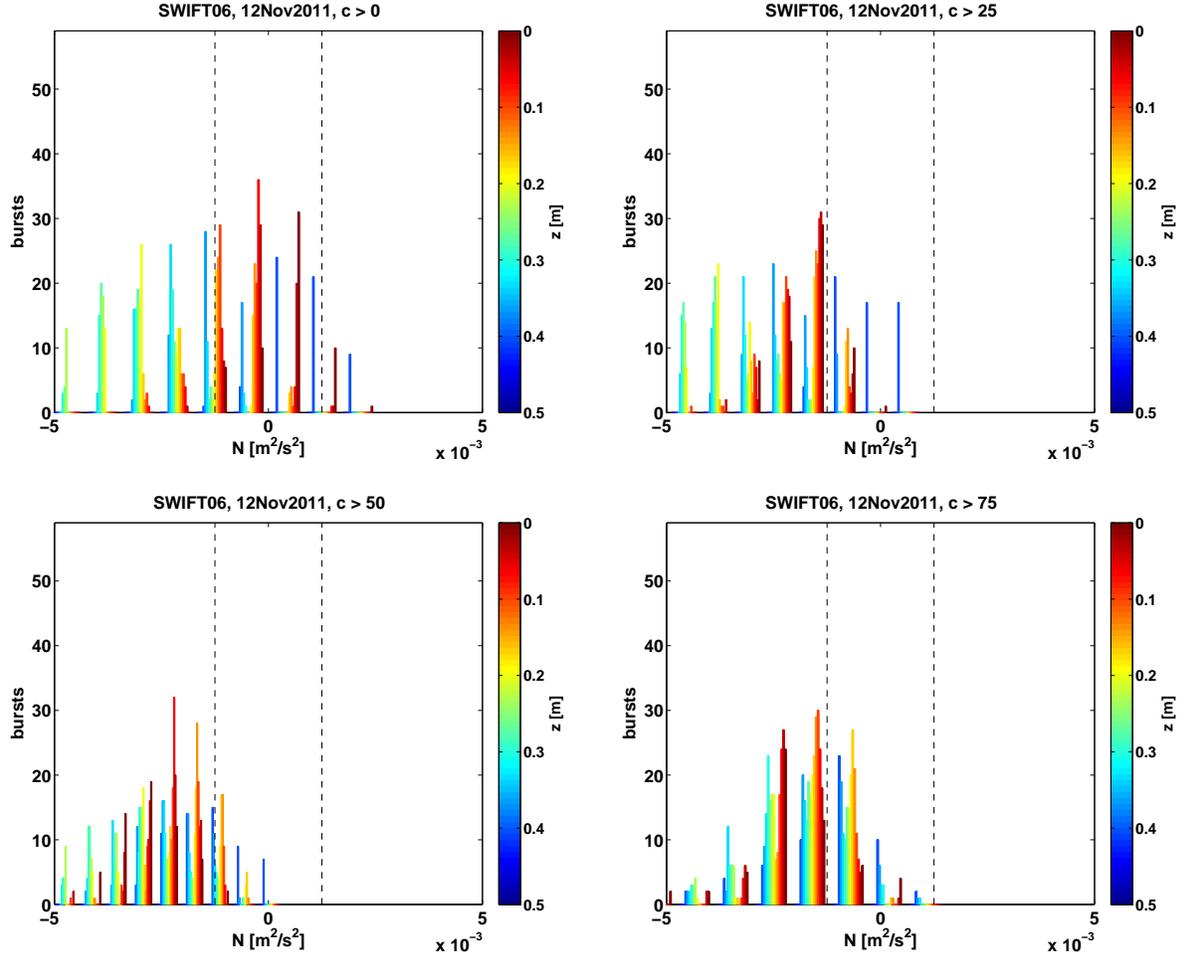

FIG. 11. Distributions of noise intercepts N from all bursts on Lake WA using four different pulse correlation cutoffs for quality control of velocity data. Clockwise from upper-left: $c > 0, c > 25, c > 75, c > 50$. Colors indicate depth beneath the wave following surface, as in Figure 8. Dashed lines indicate the expected range for N , given a Doppler velocity uncertainty of $\sigma_u = 0.025$ m/s.
